# MINNESOTA DEPARTMENT OF NATURAL RESOURCES SECTION OF FISHERIES 

Completion Report

Estimating Angling Pressure, Catch Rates, Structure of Catch, Recreation Use, and Walleye Exploitation on Fish Lake Reservoir, St. Louis County, Minnesota using a Stratified Random, Roving Creel Survey (May $14^{\text {th }}, 2005$ to February $26^{\text {th }}, 2006$ ).

Influence of Fishing Location Choice on Fishing Success during the Early 2005-06 Ice-fishing Season on Fish Lake Reservoir.
by

Jonathan R. Meerbeek

This project was funded in part by the 1854 Authority and Fond du Lac Division of Natural Resources through the Federal Aid Sportfish Restoration Program, grant number U-4-NA-1

## CHAPTER 1

## ANGLER CREEL AND RECREATIONAL USE

## INTRODUCTION AND STUDY AREA

Fish Lake Reservoir is the third largest (3,071 acres) of five headwater storage basins in the St. Louis-Cloquet system created by Minnesota Power (MP) in the early 1900's for the purpose of hydroelectric power generation. Fish Lake Reservoir is operated by MP, with maximum power generation occurring from late fall through late winter. The reservoir is typically refilled to full pool (18.5 ft ) by June $1^{\text {st }}$. Seasonal water level fluctuations are common, but since the Federal Energy Regulatory Commission (FERC) relicensing in 1995, the magnitude of drawdown has been less drastic (maximum drawdown elevation of 14 ft ) and is most dependent on seasonal rain and snowfall accumulation in the watershed and power generation needs.

Northeast Minnesota rivers and lakes were formed primarily through scouring of Precambrian rock by glacial ice sheets and are typically the most unproductive in Minnesota (Schwartz and Thiel 1954; Moyle 1956); however, man-made reservoirs have accelerated rates of eutrophication and are generally much more fertile. Fish Lake Reservoir is classified as mesotrophic and is one of the most productive water bodies in lower St. Louis County (Carlson’s Trophic Index; Citizen Lake-Monitoring Program). Over $75 \%$ of the reservoir is littoral ( 2,303 acres) and depths reach a maximum of 31 feet. Most of the shoreline is owned by MP, which leases out lots to private individuals for development. Currently, about 195 homes or cabins are located along the shoreline of Fish Lake Reservoir.

The Fish Lake Reservoir management plan primarily focuses on preservation of quality angling. Fish Lake Reservoir supports sport fisheries for walleye, northern pike, yellow perch, black crappie, bluegill, and most recently, largemouth bass. Walleye, northern pike, and yellow perch were native to the original Fish Lake and Moose lakes and the interconnecting waterways. Black crappie and bluegill were introduced between 1924 and 1944. Largemouth bass were not identified in any large number
until the fall young-of-the-year (YOY) walleye investigations in 2004 and 2005 when Minnesota Department of Natural Resource (MNDNR) fisheries crews caught numerous age-1 and older fish. No largemouth bass were observed during similar investigations between 1994 and 2003. The source of the introduction of largemouth bass is unknown.

Fish Lake Reservoir has been stocked with over 22 million walleye fry between 1924 and 1989. Minnesota DNR conducted a population assessment in 1989 and found that only $28 \%$ of aged fish correlated to fry stocked years. Subsequent surveys and assessments showed similar trends of constant recruitment in the absence of stocking and stocking was deemed unnecessary. Young-of-the-year walleye abundance was annually indexed between 1994 and 2005 via fall electrofishing. Catch rates of YOY walleye were always near the best in the Duluth Area, but abundance did fluctuate in response to environmental conditions in the spring. The age structure of the walleye population in 1993, 1996, 1999, and 2005 also resembled erratic recruitment patterns. Results from a mark-recapture experiment for walleye in 1999 estimated a population of approximately 46,200 walleye (Borkholder and Edwards 2000).

Because of its large size and close proximity to Duluth, Fish Lake Reservoir has been a popular destination for general angling and tournament fishing contests. No creel survey has been done on Fish Lake Reservoir. An aerial recreational use survey of 67 Duluth Area lakes was conducted between 1999 and 2000 and estimated approximately 69,186 total angling hours (Rust 2001). Fishing pressure was categorized as moderate to heavy with 21.2 anglers hours per acre. The lake has historically supported a popular walleye fishery. In addition, a strong 1988 black crappie year class produced several years of excellent angling.

The predaceous exotic zooplankton spiny water flea (Bythotrephes cederstroemi) was detected in Fish Lake Reservoir by the University of Wisconsin-Superior in the mid 1990s. The spiny water flea feeds primarily on daphnids and copepods and could reduce the abundance of food items available to planktivorous fish, which could negatively impact gamefish recruitment. However, even when the
spiny water flea occurs in high densities, no impacts to gamefish recruitment were observed in Island Lake Reservoir, St. Louis County (Lindgren 2006).

In 2005-06, Fish Lake Reservoir was included in a joint MNDNR, 1854 Authority and Fond du Lac Division of Natural Resources study of walleye exploitation rates within the 1854 ceded territory of Minnesota. Several years of spring electrofishing investigations suggested that walleye exploitation rates in several Grand Marais Area lakes might be relatively high. Based on age distribution and catch curve analysis, Fish Lake Reservoir walleye population was thought to have somewhere between 29 and $39 \%$ annual mortality (unpublished data), which is about average for exploited populations. Therefore, Fish Lake Reservoir was selected as a control so comparisons could be made between lakes thought to have high walleye exploitation and lakes thought to have average walleye exploitation. Other objectives of the study were to estimate specific catch rates, structure of catch, angling pressure, total harvest, and amount of recreational use.

## METHODS

## Creel Survey Design

A random roving, stratified creel survey was determined to be the best survey method for this reservoir due to the high number of cabins and permanent homes on the lake. The survey was stratified by season (five), day type (two), and time of day (day period; Table 1). Seasonal strata were spring (May 14, 2005 - June 30, 2005), summer (July 1, 2005 - August 31, 2005), fall (September 1, 2005 October 31, 2005), early winter (December 1, 2005 - January 15, 2006), and late winter (January 16, 2006 - February 26, 2006). Day types were weekends (including holidays) and weekdays. Within each seasonal stratum, all weekends/holidays were sampled and weekdays were selected randomly.

Open water Creel
The open water fishery was sampled from May $14^{\text {th }} 2005$ to October $31^{\text {st }}$, 2006. Days were divided into two periods (AM and PM), selected to represent the entire daylight time (Table 1). Five
eight-hour workdays were creeled each week. Each scheduled day started at one of four randomly selected locations (Figure 1) and moved around the lake in a clockwise or counterclockwise direction (determined randomly). The creel clerk performed two instantaneous counts randomly scheduled throughout the workday. At the beginning of a shift, the clerk reported to the assigned start location and interviewed anglers as encountered, moving in the direction assigned. At the scheduled count time, the creel clerk would stop interviewing anglers and circumnavigate the reservoir, counting the total number of bank anglers, dock anglers, boat anglers, and recreational users. Recreational users were defined as those individuals utilizing the reservoir for purposes other than fishing.

Interviews were conducted on a party basis. Information collected relative to the trip included: access used (public, private, resort), activity type (e.g. fishing, pleasure boating), time spent fishing, status of the trip (complete or incomplete), angler type, number of anglers, target species, fishing method, lure type, boat and motor type and size, presence of trolling motor, use of electronics, age, gender, and angler residence (zip code). Information relative to catch included: species and length of harvested fish, and species and number of released fish. The clerk measured all harvested fish to the tenth of an inch. The creel clerk recorded tag numbers from all observed tagged walleye and thoroughly checked other harvested walleye for signs of tag removal or tag loss. When lengths of released and harvested fish were unavailable for measurement, anglers were asked to estimate the size of each fish. Interviews were randomized both temporally and spatially on days when the clerk was unable to interview every party on the reservoir.

To increase the amount of completed-trip interview data collected, most incomplete fishing parties interviewed were given a simple postcard questionnaire (postage-paid) addressed to the area fisheries office. The clerk was required to fill out the date of the interview along with the interview number prior to handing out the postcard questionnaire. Anglers were asked to fill out and mail the questionnaire at the end of the fishing trip. Anglers were asked to provide information on party size
and the duration of fishing trip, number and size of harvested and released fish, and the tag numbers from any fish harvested.

## Winter Creel

The winter ice fishery was sampled from December $3^{\text {rd }}, 2005$ to February $26^{\text {th }}$, 2006. The survey was stratified by season and day type (Table 1). Angler types identified were ‘open ice’, 'fish house (portable and permanent)' and 'spear'. Pressure and catch statistics were calculated separately for each angler type. Because of decreasing day length, only one day period was used during the winter creel. The creel clerk worked four 10-h days per week; two weekend days and two randomly selected weekdays.

Winter creel interview and count procedures were similar to the open water creel methods except the clerk used a snowmobile or all-terrain vehicle (ATV) to access anglers. The creel clerk counted all open-ice anglers and all occupied permanent fish houses and portable fish houses during two random count times within the 10 -hour shift. An ice shelter (inside angler) was determined as occupied if there is a vehicle parked next to it, if there was smoke from a chimney, if there was a noticeable heat source from within or a portable propane tank outside the shelter, or if there were fresh tracks in the snow leading from a nearby cabin. Only occupied fish houses and open-ice anglers were used in the calculation of total fishing pressure. The winter postcard questionnaire resembled that of the postcard used in the open water creel.

## Walleye Exploitation

Between April 16-19 2005, Fond du Lac Band and 1854 Authority captured and marked 2,568 walleye ( $\geq 10$ inches) with individually numbered floy tags and then released them back into the lake. Drop boxes and educational signs were placed at five access sites (two public landings and three resorts) to inform the public and collect tags returned voluntarily by anglers over the 2005 fishing season. Harvested tagged walleye information was also gathered by handing out postage-paid postcards to interviewed anglers who had not completed their fishing trip. The creel clerk also recorded any tagged walleye harvested during the scheduled shift. The absolute minimum mortality estimate
was calculated by adding all sources of known harvested tagged walleye (observed during creel, drop boxes, phone calls, mail-ins) and dividing by the number initially tagged $(2,568)$. Estimated exploitation over the entire fishing season was calculated by using the estimated number of tagged walleye harvested in the creel divided by the total number initially tagged.

## Analysis

Fishing pressure, catch rates, targeting catch rates, harvest (number of fish), and yield (pounds of fish) for each season and combined open water and winter periods were estimated using the GENCREEL program (Bindman and Mach 1994). Mean lengths and associated standard errors for harvested fish were calculated by pooling data for fish lengths measured by the creel clerk over the entire season. Length frequency distributions for fish harvested and released were expanded by multiplying the ratio of each length group in the measured sample by the estimate of the total harvest. Individual weights were calculated for all measured fish using length-weight relationships determined from fish population investigations conducted between 1993 and 2005 (Table 2). Calculated individual weights were pooled over the entire season and used to estimate mean weights in the same way that mean lengths were determined.

To determine harvest and catch rates for tagged and untagged walleye, untagged walleye were assigned a species code of WAE and tagged walleye were coded as WAT. When estimates for all walleye were required, the GENCREEL program was run using the code WAE for both tagged and untagged walleye.

The mean length of completed fishing trips, the percentage of parties using various accesses and fishing methods, and the percentage of anglers residing in various locales was determined by pooling interview data for both the open water and winter fishing season. Angler residence (city and state) was determined from zip codes reported by anglers using the computer program "Zipkey" (Isaacson 1991).

Returned questionnaires for each season were pooled for the calculation of harvest and release rates and for summarizing return rates. Harvest and release rates were determined by the ratio-of-means
method: dividing the mean number of fish caught per party by the mean hours fished per party (number of anglers times trip length; Murphy and Willis 1996).

## RESULTS AND DISCUSSION

## Fishing Pressure

Total estimated fishing pressure for Fish Lake Reservoir during the 2005/2006 fishing season was 79,394 hours (Tables 3 and 4). Over $36 \%$ of all fishing pressure occurred during the spring and pressure during this period was two to three times higher than all other seasons except summer. Most lakes that have good populations of sport fish have elevated fishing pressure during the spring when fish concentrate in spawning locales and metabolism increases. Lindgren (2004) estimated that over $70 \%$ of angling pressure occurred during the spring in the nearby St. Louis Estuary. Although angler effort in Fish Lake Reservoir was high during the spring, significant fishing pressure occurred during all seasons, which is uncommon for many Duluth area lakes (Rust 2001; Lindgren 2004). Fishing pressure in the summer in Fish Lake Reservoir was about one-third less than spring, but was higher than all other seasons. When combined, fishing pressure during the open water period accounted for $72 \%$ of all fishing pressure (Table 3). About 22,000 angling hours were spent fishing thru the ice with nearly $60 \%$ of this effort occurring during the early winter (Table 4).

Fish Lake Reservoir received approximately 25.8 angler hours per acre during the 2005-06 fishing season (Table 5). The estimated fishing pressure in this study was remarkably similar to what was observed by Rust (2001) during an aerial recreational use survey (21.2 h/acre). Rust (2001) also estimated fishing pressure for other reservoirs within the St. Louis River/Cloquet river system, but fishing pressure in those systems was one-third to one-half less than what Fish Lake Reservoir received. Contrary to most other large lakes or reservoirs in the area, Fish Lake Reservoir supports both a significant summer and winter fishery (Table 5). The only other water body within the Duluth Fisheries Management Area supporting a similar amount of fishing pressure is the St. Louis Bay Estuary, but
almost all of the pressure in the Estuary occurred in the open water season (Lindgren 2001). Fish Lake Reservoir has substantially more open water fishing pressure when compared to other lakes within lake class 7; however, total fishing pressure was about $25 \%$ less when compared to statewide averages (Cook and Younk 1998; Table 5).

During the open water creel, boat anglers accounted for nearly $88 \%$ of all hours spent fishing, of which, $42.2 \%$ occurred during the spring and $31.6 \%$ during summer (Table 3). Shore angling was popular during the spring along County Road 48 causeway and along the dam. Although numerous lakeshore properties are located along the shore of Fish Lake Reservoir, very few residents fished from their docks during any part of the open water creel (Table 3). Less than $1 \%$ of total open water angling hours was spent fishing from docks.

Most anglers that fished during the winter used either a portable or permanent fish house and accumulated an estimated 18,882 hours of fishing effort (Table 4). Over $86 \%$ of the fishing pressure was conducted by fish house anglers, followed by open ice anglers (13.7\%) and spear anglers (0.3\%). Open ice anglers were more frequently observed during the late ice period when ice conditions were safe for driving vehicles, snowmobiles, or ATV's. Spear anglers were rarely interviewed and fishing pressure was very low (Table 4).

## Harvest and Yield

Black crappie total harvest and yield was low (1,451 fish and 852 pounds); however, there were noticeable differences in harvest among seasons (Tables 6 and 7). Of all black crappie harvested, 71\% were harvested in either fall (48\%) or late winter (23\%). Angler reports and anecdotal evidence suggested that black crappie harvest might be very high during the fall and winter months, especially during the early 1990’s when a large 1988 black crappie year class reached adult size (Duluth Area lake management files). However, results from this study suggest that black crappie do not represent a large proportion of total harvest (7.4\%) and yield (4.1\%). Marginal year classes since the late 1980’s were most likely
responsible for reduced harvest and yield of black crappie since the late 1990's (Duluth Area lake management files).

The mean length of black crappie harvested was 10.1 inches during the open water creel and 9.6 inches during the winter creel (Table 8). Most anglers did not harvest black crappies that were 7 inches or less during either period; however, almost all black crappie over 9 inches were harvested (Tables 9 and 10). Anglers that fished the St. Louis Estuary had similar perceptions of harvestable and released sizes of black crappie (Lindgren 2004). Of the angler parties interviewed, no party harvested more than 10 black crappies during a single fishing trip during any season and only a few harvested a single black crappie (Table 11).

Anglers harvested an estimated 4,167 bluegill during the 2005-06 fishing season, which represented $21.4 \%$ of all fish harvested and $7.1 \%$ of the yield (Tables 6 and 7). Bluegill harvest was highest during the spring and summer months, lowest in fall and early winter, and then increased in late winter. Over $81 \%$ of bluegill were harvested during the open water creel. The mean length of bluegill harvested was similar among the open water (7.9") and winter (8.1") seasons; however, winter anglers released a higher percentage of small fish (<6.0"; Tables 8-10). Bluegills are colonial nest spawners and males aggressively defend nests (Moyle and Cech 2000); therefore, targeting anglers can easily catch adult bluegill during the spawning period once spawning grounds are found. It is likely that increased harvest and size of bluegill caught during the spring and summer months could be attributed to this event. However, even when fishing was at its peak (e.g. spring and summer), less than $1 \%$ of anglers harvested more than 7 bluegill during a fishing trip (Table 12).

Anglers harvested very few (127) largemouth bass during the 2005-06 fishing season (Tables 6 and 7). Most catch or harvest of largemouth bass occurred during the summer and fall (Table 9). Largemouth bass were nearly absent from the winter creel (Table 10). Only during the fall did anglers catch or harvest more than one largemouth bass (Table 13). Although the bass population in Fish Lake Reservoir is relatively new, the size and habitat complexity of the reservoir may be conducive for this
species. At least three year classes have been identified by MNDNR fisheries crews and reproduction since 2003 has been good (Duluth Area Fisheries Management files). Angler awareness coupled with increased population size should increase harvest and yield in the future.

Approximately $13 \%$ of fish harvested in 2005-06 were northern pike, which accounted for $36.9 \%$ of the total yield (Tables 6 and 7). Although northern pike yield was always high, significant seasonal differences were observed. Northern pike harvest and yield was highest in the spring and winter seasons and lowest during the summer and fall. Fewer anglers targeted northern pike in the spring as opposed to the summer and fall, but much more effort occurred during the spring, therefore increasing harvest and yield. In contrast, anglers more frequently targeted northern during the winter period and even with much less fishing pressure (as opposed to spring), harvest and yield were nearly identical (Tables 6 and 7).

Generally, anglers released all northern pike smaller than 15 inches and harvested fish larger than 22 inches (Tables 9 and 10). Northern pike harvested during the winter period were substantially larger than those harvested during the open water period; however, released northern pike were of similar size (Table 10). One explanation for increased sizes of harvested northern pike during the winter period was that more anglers targeted that species. Northern pike were frequently caught and harvested by anglers as by-catch during the open water period when anglers primarily targeted walleye. Over $3 \%$ of anglers harvested three or more northern pike in the spring, compared to $1 \%$ in the summer and $0 \%$ from fall to late winter (Table 14). However, the percent of anglers harvesting northern pike was much higher during the winter creel, suggesting a preference towards that species.

An estimated 8,738 walleye ( $9,174 \mathrm{lbs}$ ) were harvested during the 2005-06 fishing season representing over $40 \%$ of the total catch and yield, which was the highest of any species (Tables 6 and 7). Fifty-six percent of all harvested walleye were caught in the spring; however, walleye did comprise a significant proportion of the harvest in all other seasons except late winter. Anglers began harvesting walleye when they reached 10 inches (Tables 9 and 10). The mean length of walleye harvested in the open water period was about one-half inch less than those harvested in the winter (Table 8); however,
those harvested in the St. Louis Estuary were about 2-3 inches longer in any season (Lindgren 2004). The larger size of harvested walleye was expected in the Estuary because regulations only allow for harvest of two fish with a minimum size limit of 15 inches and walleye growth is faster. Walleye regulations in Fish Lake Reservoir fall under the statewide regulation of a 6 fish daily bag limit and no size limit. Even with these more liberalized bag and size limits, few anglers or angler parties ever harvested six or more walleye during any season in Fish Lake Reservoir (Table 15). Enforcing a minimum size limit similar to that of the St. Louis Bay may increase size structure of caught walleye, but minimum size limits of 15 inches typically do not increase walleye catch rates or growth (Fayram et al. 2001). In order to make a biological impact on the number of walleye caught per trip, daily bag limits would need to be decreased to two fish per day, which may be socially unacceptable.

Nearly 2,400 yellow perch (1,257 pounds) were harvested during the 2005-06 fishing season, representing $12.3 \%$ of the total harvest and $6.1 \%$ of the yield (Tables 6 and 7 ). As with most species, seasonal differences in harvest were detected with the highest harvest occurring during the spring (39.6\%) and early winter (30.5\%). The size of harvested and released yellow perch was larger in the open water period as opposed to the winter period (Table 8), but the size structure of catch was similar among periods (Tables 9 and 10). Winter anglers harvested a higher percentage of smaller (8.0-9.0 inch) yellow perch, thus decreasing mean length at harvest and release (Tables 9 and 10). Yellow perch were rarely targeted by anglers during the open water period, but were often targeted during the winter period. In addition, angler's targeted black crappie and bluegill more frequently in the winter period and yellow perch were often caught as by-catch and frequently included in an angler's daily bag. However, no angler or angler group that was surveyed in this study caught a limit (20 fish) of yellow perch and only a few anglers’ harvested more than 3 during a fishing trip (Table 16).

Of all the completed trip interviews that were conducted on Fish Lake Reservoir during the 2005-06 fishing season, few anglers or angler groups harvested a limit of any fish species (Tables 11-16). However, most anglers caught at least one or more fish during a fishing trip, with highest catch potential
occurring in spring (Table 17). In addition, anglers were more harvest oriented during the spring, early winter, and late winter periods.

## Harvest, Release, and Catch Rates

Black crappie harvest, release, and catch rates for all anglers were low during all seasons except fall in Fish Lake Reservoir (Tables 18 and 19). Harvest rates generated from angler questionnaires were very similar to what was observed by the creel clerk in both the open water and winter surveys (Table 20). Over $23 \%$ of angling parties targeted black crappie during the fall and late winter seasons and harvest rates during those seasons were among the highest observed (Tables 21 and 22). Compared to the St. Louis Estuary and state median values, black crappie harvest rates were much lower for targeting anglers (Cook and Younk 1998; Lindgren 2004; Table 23). Black crappie fishing opportunities in Fish Lake Reservoir are minimal, except for occasional years following strong year-classes.

Bluegill harvest, release, and catch rates in Fish Lake Reservoir were highest in the summer (Tables 18 and 19). Harvest rates of bluegill were also good during the spring and late winter seasons. Anglers that returned questionnaires also had better angling success during the open water period (Table 20). Bluegill catch and harvest rates for targeting anglers were always the highest compared to other targeted fish species, with the highest percentage of anglers seeking bluegill during the summer and late winter seasons (Tables 21 and 22). Harvest rates for anglers targeting bluegill in Fish Lake Reservoir were about one-half the state median, but were higher the St. Louis Estuary (Table 23).

Harvest and catch rates of largemouth bass in Fish Lake Reservoir were the lowest of any species and were not a significant proportion of anglers catch during any season (Tables 18 and 19). A few anglers did target largemouth bass during the summer and fall, but their catch and harvest rates were also low (Table 21). The largemouth bass fishery in Fish Lake Reservoir appears to be very minimal.

Catch rates of northern pike in Fish Lake Reservoir were generally best in the open water seasons; however, harvest rates were highest during the winter period (Tables 18 and 19). A similar pattern of increased harvest and decreased catch rates during the winter period was observed from
returned questionnaires (Table 20). More anglers targeted northern pike during the winter months, which may have increased harvest rates (Table 22). Harvest rates of northern pike by targeting and nontargeting anglers in Fish Lake Reservoir were higher than the St. Louis Estuary and the state median (Table 23). The northern pike fishery has proven to be a valuable resource to anglers, especially during the ice-fishing season.

Walleye catch rates were highest in the spring and fall, average in the summer and early winter, and lowest in the late winter (Tables 18 and 19). Harvest rates followed a similar trend and were usually about one-half of the total catch rates. According to angler returned questionnaires, walleye harvest and catch rates were about twice as high during the open water period and about four times higher during the ice period when compared to harvest and catch rate estimates using observed creel clerk data (Table 20). Inflated catch estimates are not uncommon when using angler reported data because anglers that catch fish are more likely to report that data than those who catch few or no fish. Interestingly, catch rates for most other species do fall within a similar range when comparing the two different estimates. One explanation for this is that walleye are a much more sought after fish than most other fish species; therefore, the tendency for anglers to correctly fill out other species information is much higher.

Since most anglers that fished during the open water period targeted walleye, few differences were observed among catch or harvest rates for targeting and non-targeting anglers (Tables 18 and 21). Fewer anglers targeted walleye during the winter period, but of those anglers that did target walleye, catch and harvest rates were about one-third higher during early winter and three to four times higher in late winter (Tables 19 and 22). Harvest rates of walleye in Fish Lake Reservoir were similar to the St. Louis Estuary and state median values (Table 23).

Although yellow perch catch rates were high among all seasons, harvest rates were always less than 0.07 fish/hr (Tables 18 and 19). Harvest rates from angler questionnaires were nearly identical to what was observed by the creel clerk in both the open water and ice surveys (Table 20). Less than $0.5 \%$ of anglers or angling parties targeted yellow perch during the open water period, while 3-4\% of anglers
targeted them during the winter period (Tables 21 and 22). Yellow perch appear to be a more important sport fish during the winter months in both Fish Lake Reservoir and the St. Louis Estuary, but harvest rates were much less than the state median (Table 23).

## Angler Demographics

Local residents accounted for 92\% of the anglers interviewed on Fish Lake Reservoir in 2005-06 (Table 24). Only 55 anglers (1.0\%) were from Superior or other nearby Wisconsin towns. Out-of-state license fees probably deter many Wisconsin anglers, even though the reservoir is located only a few miles from Superior. Anglers residing in the St. Paul - Minneapolis Area were the only other angling group that accounted for a noteworthy proportion of anglers. Fish Lake Reservoir was a top destination choice for the residents surrounding the Duluth Metropolitan Area.

Average party size and trip length was 2.07 anglers and 4.08 hours during the open water period (Table 25). Most of the angling during the open water period was conducted by boat anglers (Table 24). Anglers most frequently used the public access near the dam; however, a fair number of anglers used boat ramps located at resorts (Table 26). Still fishing using a minnow or a mixture of leeches, minnows, or worms was the most popular fishing technique among open water anglers. Nearly $88 \%$ of all boat anglers used electronics of some kind to aid in locating fish or fishing sites.

Average party size and trip length was 1.73 anglers and 3.61 hours during the winter period (Table 25). Ice anglers most commonly used portable fish houses; however, numerous anglers fished from permanent fish houses or used no fish house (Table 24). About 60\% of ice anglers "still" fished while the remaining $40 \%$ used a combination of jigging and tip-ups (Table 26). Anglers that used tip-ups were primarily focused on catching northern pike, but occasionally, walleye were also taken from tip-ups. Anglers used almost exclusively minnows, or a mixture of minnows and wax worms during the ice period. Over $60 \%$ of ice anglers used a flasher, camera, or locator when angling. Many anglers commented on the large number of walleye, northern pike, and small yellow perch observed when using a camera device, but few could get those fish to bite. When spring and summer conditions are right, the
high productivity of the reservoir allows for good year classes of forage fish such as shiners and yellow perch. Environmental conditions during the spring and summer of 2005 were favorable for these species, therefore, top-level predators were not as hungry and angling was more difficult.

## Walleye Exploitation

An estimated total of 490-tagged walleye were harvested from Fish Lake Reservoir during the 2005-06 fishing season (Table 27). Walleye fishing mortality was low at only $19.1 \%$, with most (18.4\%) mortality occurring during the open water period. Based on age distribution catch curves from walleye netting in 1996, 1999, and 2005, total annual walleye mortality in Fish Lake Reservoir ranged from 29 to 39\% (unpublished data). Using these estimates of annual and fishing mortality, annual natural mortality for walleye ranges from 10-20\%, which is within the range of mortality rates for adult walleye in North America (13-80\%) reported by Colby et al. (1979) and similar to those observed from Kansas Reservoirs and several Wisconsin lakes (Beard et al. 2003; Quist et al. 2004). A total of 341 tags from harvested walleye were recovered from either drop boxes (179), observed by the creel clerk (73), or phoned or mailed-in (89), which resulted in an absolute minimum mortality estimate of $13.3 \%$. This estimate is low since not all anglers were anticipated to cooperate with tag returns, however, an absolute minimum mortality estimate may be useful when modeling population effects because mortality is known at some level of certainty.

## Conclusions

The open water and winter fishery on Fish Lake Reservoir has proved to be substantial. Fishing during the 2005-06 fishing season was generally considered to be good. Angler pressure was near the highest in the Duluth Area, but still below the state median values for lake class 7 lakes. A significant seasonal difference in fishing pressure was observed, with the highest pressure during the open water period, especially spring. Walleye and northern pike contributed the most to annual yield, but several other species were seasonally important to anglers. Walleye fishing mortality was $19.1 \%$ and was considered low to average compared to other reservoirs and area lakes.

## CHAPTER 2

# INFLUENCE OF FISHING LOCATION CHOICE ON FISHING SUCCESS DURING THE EARLY 2005-06 ICE-FISHING SEASON ON FISH LAKE RESERVOIR 

#### Abstract

Random-roving fisheries creel surveys are designed to collect information on catch, harvest, fishing pressure, and human demographics. Although creel clerks often encounter anglers while in the act of fishing, information regarding choice of fishing location as it relates to angler success is usually ignored. Using creel survey data along with GPS data obtained during the early 2005-06 ice-fishing season, success of anglers concentrated within distinct fishing locales (i.e. cluster anglers) was compared to that of isolated anglers (i.e. anglers fishing alone or in small groups). The objective of the study was to quantify and compare differences in catch and harvest rates, species composition, and size of fish caught between the two groups. Anglers that fished in isolated areas caught $56 \%$ more and harvested $21 \%$ more fish than anglers fishing in clusters. Isolated anglers harvested more and larger walleye and caught substantially more northern pike than cluster type anglers did, but harvest rates and size of northern pike were similar. Yellow perch and black crappie were caught at similar rates between angling groups; however, more and larger yellow perch were harvested from cluster areas. Bluegills were more often targeted by isolated anglers and catch and harvest rates were 31 to 34 times higher than for those anglers fishing in clusters.

## INTRODUCTION

The Minnesota Department of Natural Resources (MNDNR) has conducted creel surveys on over 1,000 water bodies to estimate recreational harvest (Cook et al. 1997). Many of these surveys were conducted as random-roving creel survey's, where creel clerks often interview anglers and record their catch during the anglers fishing trip. Many variables may influence fishing success in terms of catch and harvest rates at any given time (i.e., angler skill, fishing location, weather patterns, bait/lure type, etc.),
making the prediction of fishing success difficult. Correlations between fishing site location and fishing success have been observed in several coastal and inland fisheries (Kangas 1995; Hutton et al. 2004; Smith 2005). In any water body that receives a fair amount of winter ice fishing pressure, two angler types are usually found: those that fish in groups and those that avoid large congregations of anglers. Variables that may influence an angler's daily choice of fishing location include accessibility, past success, remoteness or affinity to crowds, and amount of allotted fishing time. The objective of this study was to quantify and compare differences in catch and harvest rates, species composition, and size of fish caught between anglers concentrated within distinct fishing regions (i.e. cluster anglers) to that of isolated anglers (i.e. anglers fishing alone or in small groups) during the early ice fishing season (December 3, 2005-January 16, 2006) on Fish Lake Reservoir.

## METHODS

A standard stratified random-roving creel survey was conducted during the early winter icefishing season (December 3, 2005 to January 16, 2006). In addition to time fished and catch statistics, creel clerks recorded angler location after each "on-ice" interview using a Garmin Map76 GPS unit and waypoints were downloaded using the DNR Garmin program. Anglers were classified as cluster type anglers based on the following criteria.

- Five or more permanent ice fishing shelters were observed in the same location (within a 70 m radius) throughout the duration of the study
- Anglers were interviewed from a specific area at least $80 \%$ of the total creel days ( $\mathrm{N}=27$ ). Estimation of catch, release, and harvest per hour were calculated for both angler types using the Mean-of-Ratios Estimator (Murphy and Willis 1996). One-way Analysis of Variance (ANOVA) was used to test differences in mean lengths of harvested and released fish. Significance level was determined at $\mathrm{P}<0.05$. Waypoints were converted to shapefiles and maps were made using ArcView.

## RESULTS AND DISCUSSION

Four distinct cluster groups were identified during the early ice fishing season on Fish Lake Reservoir (Figure 2). Most fishing activity occurred near public and resort access areas on the north shore, however, some anglers did travel over 500 m to reach certain fishing locales.

Based on differences in average catch rates, isolated anglers caught 29\% more and harvested 33\% more walleye than anglers fishing in clusters (Table 28). Isolated anglers also harvested and released larger walleye than cluster anglers (Table 29). Length frequency distribution of harvested walleye for both groups peaked near 375 mm (Figure 3). Isolated anglers harvested 7 walleye over 20 inches compared to only 2 over 20 inches harvested by cluster anglers. In addition, cluster anglers released fewer walleye between 275 and 325 mm than did isolated anglers. The findings from this study suggest that anglers who prefer harvesting more and larger walleye should avoid congregations of anglers and seek more distant, isolated areas.

Anglers that fished in isolated areas caught 51\% more northern pike than their counterparts did; however, harvest rates and size of fish harvested differed only slightly (Table 28 and 29). According to the length frequency distribution, the minimum size that either type of angler would harvest northern pike was somewhere near 550 mm (Figure 4). The size structure of northern pike harvested and released for both groups was nearly identical up to 700 mm , but the largest fish were more commonly caught by isolated anglers (Figure 4). Although isolated anglers may catch more fish than those fishing in clusters, the opportunity to harvest quality fish was similar, regardless of angler location choice.

Isolated and cluster type anglers caught yellow perch at similar rates; however, isolated anglers harvested fewer and smaller yellow perch than did cluster anglers (Table 28 and 29). The length frequency of yellow perch harvested and released was also highly skewed to favor cluster type anglers (Figure 5). One possible explanation for the increased size and harvest rates for cluster anglers is that more isolated anglers targeted bluegill and used smaller, more sensitive fishing gear, thus small yellow
perch were more easily caught as by-catch then cluster type anglers that primarily targeted top-level predators.

Few black crappie were caught or harvested by isolated or cluster type anglers during the study and no significant differences were detected; however, there was a significant difference in bluegill catch and harvest between the two groups (Tables 28 and 29; Figure 7 and 8). Bluegills were more often targeted by isolated anglers and catch and harvest rates were 31 to 34 times higher than for those anglers fishing in clusters.

When combining all species catch and harvest statistics, anglers that fished in isolated areas caught $56 \%$ more and harvested $21 \%$ more fish than anglers fishing in clusters (Table 28). The size structure of harvested and released fish was rather similar between the two groups, with fish ranging from 100 to nearly 900 mm (Figure 8). The results from this study demonstrate that an angler's choice of fishing location during the early ice-fishing season can impact what that angler catches and harvests during an angling trip.

## ACKNOWLEDGEMENTS

Fond du Lac Division of Natural Resources, 1854 Authority, and the Minnesota Department of Natural Resources provided funding for the project. Special thanks are extended to Stuart Meintz and Steve Ingram for their outstanding service as creel clerks for this survey. Also thanks to Gerry Alberts, Steve Persons, and Keith Reeves for extensive assistance with GENCREEL setup and analysis.

Appendix 5. Postcard questionnaire given to interviewed anglers that had not completed fishing trip.

# MINNESOTA DEPARTMENT OF NATURAL RESOURCES SECTION OF FISHERIES 

Completion Report

Estimating Angling Pressure, Catch Rates, Structure of Catch, and Recreation Use on Fish Lake Reservoir, St. Louis County, Minnesota using a Stratified Random, Roving Creel Survey (May $14^{\text {th }}, 2005$ to February $26^{\text {th }}, 2006$ ).

Influence of Fishing Location Choice on Fishing Success during the Early 2005-06 Ice-fishing Season on Fish Lake Reservoir.

This project was funded in part by the 1854 Authority and Fond du Lac Division of Natural Resources through the Federal Aid Sportfish Restoration Program, grant number U-4-NA-1

[^0]:    ${ }^{\text {a }}$ Number of fish measured by the creel clerk or for which anglers reported lengths.

[^1]:    ${ }^{a}$ Number of fish measured by the creel clerk or for which anglers reported lengths.

[^2]:    ${ }^{\text {a }}$ Based on GENCREEL estimates for each season.
    ${ }^{\mathrm{b}}$ Percentages do not add to 100 due to parties seeking more than one species or no particular species.
    ${ }^{\mathrm{c}} \mathrm{N}=$ number of parties interviewed.
