John W. Enblom Aquatic Biologist

ABSTRACT

A stream survey was conducted on the Red River of the North during the autumn of 1983 and the summer of 1984. Stream characteristics and fish and wildlife habitat parameters were delineated. A total of 40 stations equalling 36.3 mi of river were electrofished in 14 study sectors. The catch was comprised of 36 fish species representing 12 families. Turbidity and deep water limited the effectiveness of electrofishing. Channel catfish and walleye were the most abundant game fish at 8.2% and 3.2% of the overall catch, respectively. The major river problems are agricultural encroachment, accelerated erosion rates and high turbidity. Continued improvements in municipal and industrial discharges are necessary to alleviate low dissolved oxygen under winter ice cover conditions. The wooded corridor and its associated edge provide critical wildlife habitat. With improved watershed management practices there is potential for increased recreational opportunity amidst a somewhat barren landscape.

This project was funded in part by Federal Aid in Fish and Wildlife Restoration FW-7-S.

INTRODUCTION

The Red River was surveyed to collect baseline data on the fish and wildlife resources of the river and its associated corridor. This survey report describes environmental conditions and provides resource management information for a variety of local, state and federal agencies as well as private organizations. The river was videotaped from the air to facilitate dividing it into study sectors and locating potential access sites. Portions of each sector were electrofished during the summers of 1983 and 1984 to determine fish population characteristics. Sector locations, electrofishing stations, river miles and access points are found in the map series following the Appendix.

PHYSICAL CHARACTERISTICS

The Red River watershed encompasses 17,500 mi² in Minnesota, 21,000 mi² in North Dakota and 800 mi² in South Dakota. The river begins in the prairie region of west central Minnesota and forms the boundary between Minnesota and North Dakota for 400 mi.

Glacial Lake Agassiz lay over northwest Minnesota 12,000 years ago. Sediment carried by glacial meltwater was deposited in the lake creating an extremely level lakebed that is the broad flat plain of the Red River valley. The river drops 200 ft in elevation from its source to the Canadian border and has an overall gradient of 0.5 ft/mi. Sectors 2 and 10 have the highest gradients at 1.3 ft/mi and 0.9 ft/mi, respectively (Fig. 1). Twenty-two riffle areas were observed on the Red River, 15 of which are in Sector 10. This higher gradient area (Sector 10) extends from Halstad to Climax and is known as "Goose Rapids". The natural river channel varies in width from 200-500 ft and the average thalweg depth was 3.0-7.0 ft during normal late summer flow.

Secchi disc transparencies ranged from 0.3-1.8 ft. There were no readings over 1.0 ft downstream of Sector 3, indicating an increasing trend in turbidity from suspended solids. The Red River flows through soils of small particle size, predominantly silt and clay, that are highly susceptible to erosion and long term suspension. The river typically carries a heavy load of suspended clay and silt particles except during the winter months when runoff is at a minimum. For substrate types and other physical characteristics by sector, refer to Appendix Table 1.

Flow Data

The source of the Red River is the confluence of the Otter Tail and Bois de Sioux Rivers. The average annual flow at this point is 519 cfs. There are 13 tributaries to the Red River that have gaging stations near their mouths. Six of these tributaries have average annual flows over 100 cfs. The Red River's principal tributaries are the Red Lake, Otter Tail and Wild Rice rivers with average annual flows of 489, 303 and 258 cfs, respectively. These three tributaries are in Minnesota. The Minnesota tributaries rise from the hilly area that was the eastern shore of glacial Lake Aggasiz. They flow westerly with rather steep gradients over the beach ridges left by the receding glacial lake before reaching the level plain of the Red River valley. Gradient is substantially lower in this flat area and channel flow capacities are frequently exceeded. The North Dakota tributaries begin on the dry, high plains to the west and are low to moderate gradient streams with generally less flow than the Minnesota tributaries. Location and flow at the time of the survey for the major tributaries to the Red River are found in Appendix Table 2.

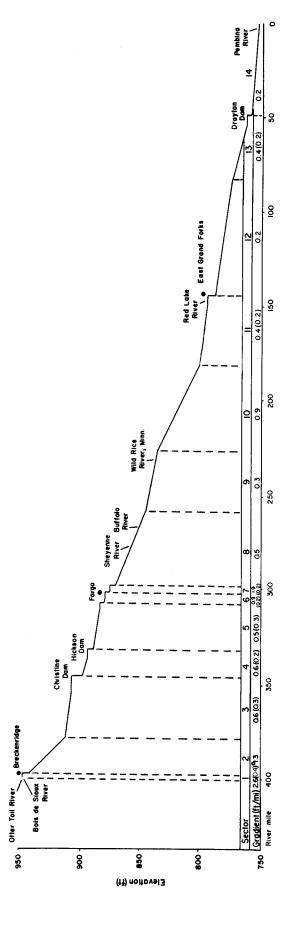

Figure 1. Red River stream profile and gradient by sector.

Dams have reduced the gradient to the figure in parentheses.

The Red River is highly susceptible to flooding due to low stream gradient, low channel capacity and the extreme flatness of its valley. Floods occur annually at some point on the main stem and the probability of a severe flood is once every seven years (Hydrologic Atlas of Minnesota 1959). The land surrounding the river is only a few feet higher than the channel banks so water spreads over an extensive area when channel capacities are even slightly exceeded. Floods can occur from March through November but are most common during April, May and June. Increased spring flows begin in the southern headwaters and may be blocked by ice cover downstream which frequently compounds flooding problems.

U.S. Geographical Survey stream gaging stations are located at Wahpeton and Fargo, ND, Halstad, MN, and Grand Forks and Drayton, ND. Average flows for the years of record at these stations and 13 major tributary stations are given in Table 1. Also shown are the average flows for the individual water years 1980-83 which demonstrate discharge variability when compared to the average flows for the years of record. Average monthly flows for the years of record show high seasonable variability as typified by the station at Drayton where the mean monthly flow ranges from 1,024 cfs in February to 14,080 cfs in April (Table 2).

Dams

There are eight dams on the Red River with the first at Wahpeton-Breckenridge used for municipal water supply (Appendix Table 3). The second dam,
near Wolverton, and the dam at Hickson, ND control river levels. There are
three dams in Fargo-Moorhead and all are used for river level control with the
furthest one downstream (RM 288.4) also used for municipal water supply. The
dam in Grand Forks-East Grand Forks retains water for municipal supply as does
the dam in Drayton, ND.

The Wahpeton-Breckenridge, Fargo and Grand Forks dams were constructed in the early part of the century for water supply. At this time low flows were common and in winter there would be times of zero flow downstream of Fargo. These dams do not effectively reduce the hazards of flooding during periods of snowmelt and heavy rains. All of the dams effectively block fish movements except during times of exceptional high water levels. This limits the dynamic nature of riverine fish populations and impairs the fishery potential.

WATER QUALITY

The Red River of the North is characteristically a turbid, grayish-brown colored stream. The color and turbidity are caused by suspended sediments scoured from the bed of former glacial Lake Agassiz which the river courses through for its entire length. Runoff from farmland and encroachment of agricultural activities have compounded this phenomenon.

Post-settlement point source pollution brought decades of degraded conditions to the Red River. Municipal and industrial wastes particularly associated with Grand Forks-East Grand Forks and Fargo-Moorhead caused serious water quality problems. Impairment of municipal water supplies, unsafe ice for commercial and domestic food storage, and the virtual extinction of fish life were the result. The drought period of the 1930's caused the most severe conditions when little or no stream flow was available for dilution. Pollution control measures within the last two decades have substantially improved these conditions.

The Red River at its source, where the Otter Tail and Bois de Sioux rivers converge, is a turbid stream with high levels of dissolved salts. The Otter Tail River contributes the majority of stream flow and although it arises in higher elevation glacial moraines as a clear unpolluted stream it

takes on the characteristics of the Red River as it cuts through beach ridges, west of Fergus Falls, and courses through the bed sediments of glacial Lake Agassiz.

Seasonal median values of water quality sampling data for the 10 year period 1974-1984 were compiled for five stations on the Red River (Appendix Table 4). USEPA Storet information for water quality sampling locations at Brushvale, MN; Fargo, ND; Perley, MN; Grand Forks, ND; and Emerson, Man. were reviewed (Appendix Table 5). Progressing from source to mouth, suspended solids, conductivity, total phosphorus and total nitrogen generally exhibit increasing concentrations. With the exception of suspended solids, these parameters frequently show seasonal reductions in concentrations at the farthest downstream monitoring station at Emerson, Manitoba. This is presumably due to the influence of the Red Lake River which joins at East Grand Forks.

Dissolved oxygen (DO), fecal coliform and biochemical oxygen demand (BOD), while not exhibiting increasing downstream trends, responded to localized influences from point and non-point source pollution. Fecal coliform levels were generally highest at Station RE-452 located upstream of the wastewater treatment facility at Fargo suggesting the discharge of contaminated stormwater or untreated sewage. BOD was generally highest at Perley, downstream of the municipal and industrial waste sources at Fargo.

water chemistry parameters necessary to support aquatic life are adequate except for winter declines of DO below the acceptable standard of 5 mg/l.

Minimum DO values in the reach from Fargo to Grand Forks are at times unacceptable for aquatic life, particularly when ice cover prohibits stream reaeration. USEPA Storet data for the winter period (Dec.-Feb.) of the years of 1974-84 record indicates that the DO was 1.5 mg/l or less 10% of the time at

Perley, 2.7 mg/l or less 10% of the time at Grand Forks and at Brushvale, downstream from Breckenridge-Wahpeton, winter values were 4.8 mg/l or less 10% of the time.

The International Garrison Diversion Study Board - Water Quality Report (1976) discussed pesticide monitoring results based on U.S. (1968-75) and Canadian (1972-76) water samples of the Red River. Organochlorine pesticides were not detected in Canadian samples but were noted in 15% of U.S. samples. Diazinon was found in 12% of U.S. samples. The chlorophenoxy herbicide 2,4-D was found in over 50% of Canadian and U.S. samples at concentrations ranging from 0.01-0.71 ug/1. A related chemical, 2,4,5-T, was detected in 5% of the total samples at concentrations of 0.01 and 0.02 ug/1.

Fish consumption advisories based on flesh concentrations of mercury and polychlorinated biphenyls (PCB) have been established by the Minnesota Department of Health. Advisories for mercury were initiated in 1970 and for PCB's in 1985. Red River fish between Breckenridge and East Grand Forks exhibited higher contaminant levels than those fish tested near the Canadian border. Channel catfish, walleye, northern pike and carp are the primary species of concern with 1986 consumption advisories varying from unlimited consumption to no more than one meal per week at six locations along the Red River.

The Red River is classified by the Minnesota Pollution Control Agency as a 1C, 2B, 3B stream. The 1C designation indicates suitability for domestic consumption with appropriate treatment. The 2B designation indicates suitability for the propagation of cool and warmwater fish and aquatic recreation of all kinds. The 3B designation indicates suitability for general industrial purposes, except food processing, with only a moderate degree of treatment. The river generally conforms to this classification; however, fecal coliform and turbidity frequently exceed the standards of 200 organisms/100 ml and 25 FTU, respectively.

WATER USES

Water Appropriation

Water is appropriated from the Red River and the Red Lake River near the mouth by seven major users. The American Crystal Sugar plants in Drayton, ND and Moorhead each appropriate 0.30 mgd (million gallons/day) from the Red River. American Crystal Sugar in East Grand Forks appropriates 0.07 mgd from the Red Lake River. Fargo and Moorhead use 10.0 and 2.65 mgd, respectively and the town of Drayton, ND uses 0.16 mgd from the Red River. Grand Forks, ND and East Grand Forks appropriate 1.92 mgd and 1.48 mgd, respectively, from the Red Lake River. There are also numerous private users that appropriate for irrigation.

Waste Discharges

The Industrial and Municipal Waste Inventory (Minnesota Pollution Control Agency 1984) lists 12 cities that discharge effluent to the Red River. The cities in Minnesota that discharge 0.1 mgd or more are Moorhead (6.0 mgd), East Grand Forks (1.4 mgd), Breckenridge (0.5 mgd) and Oslo (0.1 mgd).

American Crystal Sugar discharges 5.0 mgd of wastewater from the beet processing operation in East Grand Forks and 10.0 mgd in Moorhead when Red River flow exceeds 500 cfs (cubic feet/second). Moorhead Public Service discharges a maximum of 17.3 mgd of non-contact cooling water to the Red River.

VEGETATION

Aquatic vegetation is not common in the Red River due to the high turbidity previously discussed in the Physical Characteristics section. There are occasional beds of river pondweed in Sectors 1 and 2 with the remainder of the river devoid of vegetation except for sporadic outgrowths of smartweed and sedges along the river's edge. In presettlement times, prairie was the dominant feature on the flat plains away from the river and floodplain forest dominated the river corridor. The common grass species of the prairie were bluestem, switchgrass, Indian grass and wild rye reaching an average height of 5 ft. Examples of the prairie community persist on tracts preserved by a number of public and private organizations. The bottomland forest consists of species tolerant of a high water table and frequent inundation. The elm-boxelder community is the major component of the bottomland along with green ash, cottonwood and willow. Common understory species include round-leaved hawthorn, gray dogwood and hazelnut. Bur oak and basswood occur further away from the river and on slightly higher ground with gooseberry, wild rose and Juneberry being common representatives of the shrub layer.

Agriculture is the primary land use in the valley with 81% of the floodplain used as agricultural land. Thirteen percent is wooded with the remainder consisting of native prairie and residential areas (U.S. Army Corps of Engineers 1978).

WILDLIFE CHARACTERISTICS

The Red River valley's character has changed dramatically since pre-settlement times. Gone are the herds of bison and the endless tallgrass prairie as well as a number of other native animal species that suffered habitat loss and over-harvest. Monoculture cropland has replaced the prairie and a majority of the wetlands in the main stem subbasin have been drained and converted to farmland. The wildlife habitat and cover that remains is limited to shelterbelts and woodlands.

Waterfowl habitat is marginal because there are few oxbows and marshes along the river and aquatic plants are virtually nonexistent. More favorable

conditions exist in the North Dakota pothole country and the lake-pothole area of the southeast portion of the watershed in Minnesota. Wood ducks were the most frequently observed waterfowl during the survey. The Red River corridor is used as a rest area by migrating waterfowl, shorebirds, birds of prey and other birds.

Gray partridge is the prevalent upland game bird because of abundant cropland and pastured grasslands. Sharp-tailed and ruffed grouse populations remain at low levels because of unfavorable habitat conditions. The principal pheasant range is the southern half of the Red River valley which extends to southern Polk County. Parcels of good prairie chicken habitat exist from Wilkin and Otter Tail Counties north to Red Lake County.

Beaver, mink, muskrat, raccoon and red fox are the primary furbearers in the watershed. Beaver sign were present along the entire length of the river and individual sightings were common; however, evidence of muskrat or mink was rare. Red fox and raccoon have adapted to environmental changes and are common throughout the watershed. Black bear, bobcat and wolves occasionally wander into the Red River valley but their habitat needs are not met in this part of the state and few are successful in establishing home ranges.

White-tailed deer are common along the river because of the riparian cover and available water. The river woodland habitat is enhanced where it meets agricultural land and creates an edge effect with a variety of intermediate plant species. The floodplain forest provides critical winter cover for deer and many other species in this part of the state. Moose occur sporadically and are hunted every other year in the northeastern portion of the basin. They are not native to the Red River valley but their range has expanded over the years. One moose was sighted during the survey 10 mi south of East Grand Forks.

FISHERIES

Fishery survey work was conducted on the Minnesota-North Dakota portion of the Red River of the North during September 1983 and August through September 1984. Various investigators have done fish sampling on portions of the Red River between 1895 and 1969 (Eddy et al. 1972). More recent work includes extensive seining and some electrofishing in the Fargo-Moorhead area (J. Peterka, North Dakota State University, personal communication 1985). The North Dakota Game and Fish Department completed a fishery survey on the Red River. The work involved a gill and trap net fishery survey at 10 locations between Breckenridge and the Canadian border during August, 1976.

The initial phase of the MDNR survey involved an aerial reconnaissance and videotaping of the river from Breckenridge to the Canadian border. This provided visual information to aid in establishing sample sectors, locating access sites, determining shoreline cover type and surrounding land use.

Sector subdivisions were planned by coordinating the video data with on-the-water observations made prior to the electrofishing activity. The established sector subdivisions exemplify areas of similar physical stream structure.

Electrofishing stations were located to include representative stream habitats within the various sectors. The number of electrofishing sampling stations per sector was determined by the length of the sector and diversity of habitat. Stations consisted of a single timed electrofishing run with one to five stations established per sector. A total of 40 stations were established in the 14 sectors with an accumulated electrofishing time of 19.7 hours. All electrofishing was done during daylight hours. Legal descriptions for the location of each electrofishing station are found in Appendix Table 6. Stations are also plotted in the map series in the Appendix.

Turbidity and deep water were limiting factors affecting electrofishing results. Gear adjustments and capture are more difficult when observation of fish response is inhibited. Long stretches of deep channel and pools below Grand Forks were beyond the effective range of available equipment. It is assumed that there was some negative sampling bias for a number of species, particularly channel catfish, which inhabit the deeper pools.

Catch

The total catch of fish from the 14 sectors of the Red River contained 36 species representing 12 families (Table 3). Twelve additional species have been reported by previous investigators. One species <u>Hybopsis gracilis</u>, taken in the MDNR 83-84 survey, had not been reported from any Minnesota waters. The total numbers of fish for all species collected in the present survey are found in Appendix Table 7.

Although the minnows and other small fish species are an integral component of the fish community structure, they are excluded from the percent composition analysis of the catch. Life cycles of these species are generally more ephemeral and electrofishing gear is frequently less efficient for small fish. Unusually high, low or unrepresentative catches of the small fish can confound the comparative analysis of the percent composition of large fish species from one area or time to another. Sampling with electrofishing gear is also less efficient for the large fish young-of-year; however, they are included in the percent composition analysis. Percent composition for the large fish species catch is in Appendix Table 8.

Game fish, for purposes of this report, will be defined to include northern pike, channel catfish, white bass, sauger and walleye. Channel catfish were the most common game fish taken at 8.2% of the large fish species catch.

Table 3. Fish species collected or reported from the Red River of the North by various sources between 1895 and 1984^a.

Scientific Name	Family Common Name	Reference

Species nomeuclature from AFS Special Publication No. 12
Reference Numbers:

Nearly 78% of the catfish collected were from Sectors 2, 3 and 10. In Sectors 2 and 3, catfish were 19.4% and 19.5% of the catch, respectively. Sector 5 was the only location where no channel catfish were collected.

Walleye and sauger were the second and third most abundant game fish collected at 3.2 and 3.1%, respectively. No walleye were collected from Sectors 6, 11, 12 and 13. Sauger did not show up in the catch until Sector 8. Sauger were the most common below the Drayton Dam (Sector 14) where they totaled 29.1% of the catch. An unusual concentration of sauger was noted within the tailwaters of the Drayton Dam where approximately 100 sauger were observed during an unrecorded four minute electrofishing trial. Northern pike were collected in Sectors 1, 6, 11, 12, 13, and 14 with an overall catch of 1.5% of the large fish species.

Carp, collected in all sectors, were the most abundant at 18.9% of the overall catch, goldeye were second at 18.3% and shorthead redhorse were 17.8% overall. Carp ranged from 6.9% in Sector 9 to 46.9% in Sector 4. Goldeye accounted for 10 to 43% of the catch in Sectors 7-14; however, no goldeye were

Taken during an unofficial sampling run just upstream of the Red
Lake River.

Taken on a sampling run in the Bois de Sioux River, 1983

collected in Sectors 1-4 and 6. Shorthead redhorse were collected in all Sectors, except Sector 13, and totaled 37.2% of the catch in Sector 2.

The Minnesota River is comparable to the Red River in size, turbidity and dissolved solids (Table 4). Differences in overall catch per unit effort (CPUE) data between the two rivers is largely a result of dissimilarities in habitat (Table 4). The higher CPUE of the Minnesota River is in part due to the effects of the river's variable geology on the physical and chemical characteristics of the stream. The high percentage of game fish in the Red River is in part due to unusual numbers of channel catfish in Sectors 2 and 3 and sauger in Sector 14.

Table 4. Percent of the large fish catch for two groups of fish (game fish, carp and catostomids) in the Red River of the North and four tributaries with average flows greater than 100 cfs. The Minnesota River is included for comparative purposes.

River	Game	Fish	Carp and	Catostomids	Overall
	% (No.)	% (Wt.)	7 (No.)	% (Wt.)	CPUE
Red (1983, 84)	16.0	12.4	54.3	75.7	105.1
Otter Tail (1979, 80)	7.1	4.1	65.1	89.0	154.2
Red Lake (1976, 77)	6.0	6.1	67.5	74.3	118.8
Wild Rice (1976) ^b	3.8	5.0	83.7	89.0	a
Roseau (1976) ^c	39.0	25.0	48.8	72.1	88.8
Minnesota (1980-82)	11.4	8.2	71.2	88.3	150.2

aData was tabulated to show catch per acre only.

bOnly an upper portion of the river was sampled.

Conly the river portion in Minnesota was surveyed. Game fish catch includes high numbers of small northern pike and walleye.

The large fish species total weight and percent composition by weight for the study areas are presented in Appendix Tables 9 and 10. Channel catfish were found to be the most abundant game fish by weight at 7.4%. Although higher numbers of channel catfish were collected in Sectors 2 and 3, Sector 10 had the highest biomass at 20.3%. Walleye were second overall at 2.7% by weight. The highest total biomass of walleye for the study areas was Sector 9 at 11.7%. Sauger provided only 0.9% of the overall catch biomass, primarily from Sector 14, in which they were 16.6% of the catch.

Carp were the most abundant species by weight at 39.1% overall. In Sectors 4, 6, 7, 11, 12 and 13, carp composed over 50% of the catch by weight. The only other species that comprised 10% or more of the total catch by weight was shorthead redhorse at 11.8%.

A total of 2,968 fish (including small fish species) were captured in 19.7 hrs of electrofishing on the Red River. Appendix Table 11 shows the CPUE for each of the 14 sectors. Catch rates ranged from 48.4 to 366.0 fish/hr. Catch rates for large fish species ranged from 41.3 to 248.3 fish/hr with a sector mean of 106.5 fish/hr. Sector 2 had the highest large fish catch as a result of lower suspended solids, coarser substrates and higher gradient. Carp and catostomids contributed 178.6 fish/hr or 71.9% of that total. Channel catfish, the most abundant game fish, was collected at a rate of 48.3 fish/hr and 19.4% of the total large fish catch for Sector 2.

For the composite catch, carp and goldeye were the most frequently collected species at 19.8 and 19.2 fish/hr, respectively. Carp were more predominant in the upper one-third of the river and goldeye appeared to be restricted to the lower two-thirds of the river (downstream from the dams at Fargo). Shorthead redhorse were collected at a rate of 18.7 fish/hr.

Channel catfish were the most frequently captured game fish overall at 8.6 fish/hr. Walleye and sauger were second and third at 3.4 and 3.2 fish/hr, respectively. The highest CPUE for walleye was in Sectors 2, 7 and 9 with a range of 8.9-13.1 fish/hr.

The majority of the channel catfish were immature fish. Only a few young-of-year were taken. The majority of immature fish were taken from Sector 2. Electrofishing catches indicate that mature fish were distributed throughout the river; however, deepwater habitats such as downstream from Drayton dam had small catches that probably were unrepresentative of the actual population. Appendix Table 12 provides the length-frequencies of the catch for the large fish species. Few young-of-year walleye were collected. Adult walleye were collected more frequently in the river reaches downstream from Breckenridge and Fargo. Sauger occurred exclusively downstream from the dams at Fargo and became particularily abundant near the Canadian border, below the Drayton dam. Most sauger were adult or sub-adult fish 9-13 inches long.

Fish community structure was predictably responsive to physical stream parameters along the Red River. Gradient, substrate, turbidity, tributary streams, flow and dams are factors that strongly influence fish populations from one area of the river to another (Figure 1 and Appendix Table 1).

Although the Red River is characterized by low gradient and fine clay and silt substrates, those areas of river with higher gradient and coarser substrates generally had larger numbers of fish and percentage of game fish. Turbidity and chemical parameters such as dissolved oxygen may also be exerting some seasonal or areal influences on fish distribution. Although higher catch rates for game fish were often noted at the mouth of major tributaries, it is uncertain what affect tributary populations had on variable catch rates in different segments of the Red River.

Sauger and goldeye are species that prefer large river environments which may partially account for their abundance in the lower river; however, the apparent breaks in the catch data demonstrate the importance of dams relative to fish distribution. Dams on the Red River and a number of the dams on the lower portions of major tributaries effectively block fish movements except during extreme high flows.

Recent MDNR stockings include channel catfish fingerlings in 1978 (Wilkin County) and walleye fry in 1979 (Wilkin and Clay Counties). North Dakota stocked channel catfish fingerlings in Cass and Richland Counties in 1985.

Mussels

The available literature indicates that as many as 12 molluscan species in the families Amblemidae and Unionidae may exist in the Red River of the North. Extensive research on mussel distribution has been done by Dawley (1947) and Cvancara (1970). Dawley's work provides detailed mollusk survey data for all major watersheds of Minnesota. Specifically Dawley recorded 11 mussel species from the Red River. Cvancara's work is the most comprehensive to date. It includes surveys of the Red River and 18 of its tributaries south of the Canadian border. Cvancara reported taking 10 species from 26 sampling sites on the Red River during the summers of 1965 and 1966. The 1984 MDNR survey consisted of hand picking live or recently dead shells from four locations between Fargo and Grand Forks. Exact locations are shown in Appendix Table 13. A total of 10 mussel species were collected and identified (Table 6).

Table 5. Mussel species collected from the Red River of the North as recorded by three sources between 1947-1984.

CONCLUSIONS AND RECOMMENDATIONS

- 1. The Red River watershed is intensively utilized for agricultural purposes. Row crops abut the river banks in many areas and replace the more stable riparian vegetation. Restoration of the natural tree and shrub growth along the river would enhance water quality, recreational opportunity, aesthetic values, and fish and wildlife habitat.
- Improved soil conservation practices, and wetland protection and restoration throughout the watershed would reduce erosion and flooding problems while improving water quality.
- 3. Turbidity remains as the most pernicious problem affecting aquatic life, water supplies and recreation along the Red River. Turbidity resulting from suspended solids is largely the result of instream factors and non-point source pollution. However, the municipal waterworks at Fargo was a gross example of point source turbidity at the time of survey.
- 4. Continued improvements in municipal and industrial point source discharges should be implemented to reduce noncompliance for dissolved oxygen and fecal coliform.
- 5. At present, there is one designated public access site located at the source of the Red River in Breckenridge. There are undesignated sites in Halstad, E. Grand Forks and Olso, that could provide adequate access but need improvement. Additional sites should be developed below dams.

Table 13. Mussel occurence at four locations on the Red River (MDNR 1984).

Name	Source
Amblema plicata	1,4
Fusconaia flava	1,3,4
Quadrula quadrula	1,2,3,4
Anodonta grandis	1,2,4
Lasmigona complanata	3,4
Actinonaias carinata	1,2,3
Lampsilis ovata ventricosa	1,2,3
Lampsilis radiata siliquoidea	1,2,3,4
Ligumia recta	1,3,4
Proptera alata	1,3,4

Source Numbers:

- 1 River mile 267.0, near Georgetown, Clay County, Minnesota.
- 2 River mile 220.7, downstream of Halstad, Norman County, Minnesota.
- 3 River mile 201.8, near Shelly, Norman County, Minnesota.
- 4 River mile 14.9, near the mouth of Two Rivers, Kittson County, Minnesota.
